Abstract

In classification tasks, it is presumed that the number of classes of observations is balanced. While classification models usually give a heavily biased weight to the class that has higher occurrence, building an efficient classification model is likely a challenge when feeding it with imbalanced dataset observations or samples of data. This study introduces a new method for addressing imbalanced datasets in classification tasks, particularly focusing on predicting long-term deposits in banking institutions. The method involves systematic evaluation and comparison of random oversampling (ROS) and synthetic minority over-sampling technique (SMOTE) while employing meticulous feature selection to optimize classification precision. This new methodology showcased competitive performance, notably achieving an accuracy of 89.1% and a G-mean of 0.61 with SMOTE at a 500% ratio encompassing all features in Experiment 2 and an accuracy of 87.2% and a G-mean of 0.677 with ROS at a 500% ratio using the top 15 features in Experiment 3.

Keywords: Synthetic Minority Oversampling Technique, Random Oversampling, Imbalanced Data, Feature Selection. Random Forest

摘要 在分类任务中,假设观察类别的数量是平衡的。虽然分类模型通常会给出现率较高的类别赋 予严重偏差的权重,但在向其提供不平衡的数据集观察或数据样本时,构建有效的分类模型可能 是一个挑战。本研究引入了一种解决分类任务中不平衡数据集的新方法,特别关注预测银行机构 的长期存款。该方法涉及随机过采样(活性氧)和合成少数过采样技术(斯莫特)的系统评估和 比较,同时采用细致的特征选择来优化分类精度。这种新方法展示了具有竞争力的性能,特别是

在包含实验2中所有特征的500%比率下,斯莫特实现了89.1%的准确度和0.61的G均值,在活性氧为使用实验3中前15个特征的500%比率。

I. INTRODUCTION

Marketing selling campaigns are a standard method to enhance business. These campaigns target a segment of customers by contacting them through various channels such as fixed phone, mobile phone, or email. The dataset used in this paper was collected from bank marketing campaigns of Portuguese banking institutions by contacting their clients to determine if their product (i.e., bank term deposit) would be (yes) or (no). Due to the high volume of bank marketing data and imbalanced data problem, it is necessary to investigate an efficient and accurate classification model to support the data analysis process effectively. Consequently, this proposed a random forest-based study classification model to predict the anticipation in long-term deposits and handle the imbalanced data problem. In essence, the contribution of this study lies in a multifaceted investigation. First, this study delves into the appraisal of the random forest classifier (RFC) as a formidable tool for feature and predicting bank term deposits. Second, our inquiry extends to the assessment of oversampling techniques and their influence on elevating both the stability and performance of the classifier within the imbalance problem. Imbalanced data relate to categorization difficulties in which one class significantly surpasses the other. Binary classification is more prone to imbalance than multi-level classification [13]. Extreme imbalance data, for example, can be found in banking or financial data, such as our bank marketing dataset. An algorithm cannot obtain the information required to make an accurate prediction about the minority class from an imbalanced dataset. As a result, it is advised to employ a balanced classification dataset; most real-world classification issues exhibit some level of imbalance in classes, which occurs when each class does not include an equal amount of dataset. It is critical to correctly alter a developed approach to match the tasks' objectives. Otherwise, an unrobust outcome may be delivered [11].

To be clearer, suppose a dataset has two classes, A and B. The occurrence of class A is approximately 90% of the dataset, whereas the occurrence of class B is approximately 10%. However, the target prediction is mainly interested in detecting class B. In this case, when a model is trained, high accuracy results may be obtained for class A but not for class B. Instead, a correctly calibrated approach would have a lower accuracy but a significantly greater true positive rate (or recall), which indicates a robust classification performance. Such cases often occur, especially due to harmful content on the Internet and/or within complex data collection procedures, e.g., medical data. At this point, there are a few strategies that deal with class imbalance where some strategies are appropriate for most classification issues, while others may be better suited to certain levels of imbalanced data case. For the purposes of this study, these are described within the terms of binary classification. In addition, identifying the minority class is also presumed.

The primary objectives of this study revolve around mitigating the challenges posed by imbalanced datasets in the context of predicting long-term deposits within banking institutions. Specifically, this study aims to systematically evaluate and compare the effectiveness of two prominent re-sampling techniques, random oversampling (ROS) and synthetic minority oversampling technique (SMOTE), in enhancing classification model performance. Moreover, this study seeks to conduct meticulous feature selection alongside various re-sampling ratios to discern the optimal combination that maximizes classification precision. Indeed, the selection of the prediction of long-term deposits in banking institutions as the focal point of this study stems from the prevalence of imbalanced datasets in this domain, presenting practical implications. The findings from this research bear significance in real-world applications within banking and finance, offering potential strategies to refine classification models and inform decisionmaking processes, particularly where imbalanced datasets are pervasive.

II. METHODOLOGY

The methodology of this study is based on five major stages: data understanding and preprocessing, feature selection, modeling, evaluation, and analysis. Figure 1 illustrates the methodology and demonstrates the sequencing of the main stages.

Figure 1. Proposed methodology (The authors)

The following subsections describe the main stages of this methodology:

A. Understanding the Dataset

This study used a freely available dataset, namely the Portuguese Bank Marketing Dataset (PBMD), which resulted from a bank marketing campaign conducted by a Portuguese banking institution. The data is collected based on phone calls where each client is contacted more than once to determine whether the product (bank term deposit) is (yes) or (no). The target of the data is to predict whether the client would anticipate or not (yes, no) a term deposit [1], [3].

This dataset is the result of Portuguese financial institutions' phone marketing operations; they contact the client more than once to determine whether the product (bank term deposit) is (yes) or (no). more details on the dataset are described in the following section.

B. Data Prepossessing

1) Data Cleaning

Data cleaning is an essential step that handles unknown values and incorrect inputs. The classification model is adversely affected by error input and/or an incomplete record of the data, which affect its performance. This study performed the following data cleaning process:

• Eliminating not available data samples in each attribute;

• As recommended by the author of the dataset, the "feature duration" attribute is discarded from the dataset.

C. Data Re-sampling

For data resampling, this study uses random oversampling and SMOTE techniques. Random oversampling (ROSE) is used to produce synthetic data based on the bootstrap approach. It handles both categorical and continuous data by producing artificial examples from conditional density estimates of the two classes.

In brief, the ROSE package has different types of sampling methods: oversampling, undersampling, and bothsampling. The purpose of the oversampling technique (Figure 2) is to oversample the minority class. The purpose of the undersampling technique (Figure 3) is to undersample the majority class. The bothsampling technique combines oversampling and undersampling techniques. The majority class is undersampled without replacement, whereas the minority class is oversampled with replacement. Indeed, ROS sampling generates data artificially and delivers a more accurate estimate of the original data. Consequently, to balance the dataset in our experiment, we used the oversampling method [6].

Oversampling

Figure 2. Oversampling method (The authors)

Figure 3. Undersampling method (The authors)

On the other hand, when adding precise clones of minority instances to the main dataset, the SMOTE sampling technique is used to avoid overfitting. SMOTE generates new artificially similar instances by creating convex combinations of surrounding instances, which generates new instances of the minority class. As

illustrated in Figure 4, it creates lines in the feature space between minority points and performs sampling along these lines. This provides a balanced dataset with less overfitting to some extent [2].

Figure 4. SMOTE method (The authors)

D. Feature Selection

Feature selection is a crucial step in data mining because it helps eliminate irrelevant inputs [16]. In addition, it has several advantages, including simplifying model interpretation, mitigating overfitting, and reducing computational costs and training time [10], [16], [18]. When it comes to assessing feature relevance, one of the most renowned machine learning algorithms is the random forest [7], [17]. The random forest algorithm employs two key techniques: mean decrease accuracy and mean decrease impurity [12].

In the mean decrease impurity approach, random forest comprises numerous decision trees, each focusing on a single feature to divide the dataset into two sets where responses with the same values end up together. The criterion for choosing which feature to divide by is known as impurity. During the tree training process, the algorithm evaluates how each feature contributes to the reduction of impurities within a tree. This process is averaged, and the features are ranked accordingly.

E. Modeling

This study leverages the RFC, which is a well-established and widely adopted tool in the realm of predictive analytics. The selection of the RFC is underpinned by its notable prevalence in prior literature, which confirms its efficacy and utility for solving similar prediction tasks. The allure of this classifier lies in its inherent simplicity and user-friendliness, making it an accessible choice for researchers and practitioners alike. The primary objective of this modeling phase is to discern the optimal prediction methodology that excels in terms of generalization performance [14]. By deploying the RFC, this study aims to harness its powerful ensemble of decision trees to construct a robust predictive model for anticipating long-term deposits, thus contributing to the advancement of predictive modeling techniques in this domain.

F. Evaluation

This study employs the most prevalent assessment metric in the literature to assess the performance of the constructed classification model, including classification accuracy, sensitivity, specificity, and G-means metrics. Moreover, the confusion matrix serves as a foundation for these measurements. The purpose of this stage is to identify which classification model performs better in predicting tasks on the dataset used in this study. The following are the evaluation metrics equations [9], [15]:

Accuracy = $(TP+TN=TP+FP+FN+TN)_{100\%}$ (1)

 $Sensitivity = (TP=TP+FN)_{100\%}$ (2)

Specificity = $(TN=FP+TN)_{100\%}$ (3)

$$Precision = (TP=TP+FP)_{100\%}$$
(4)

In Equations 1-4, TP represents the number of true positives, FN represents the number of false negatives, TN represents the number of true negatives, and FP represents the number of false positives. As illustrated in Figure 5, they are defined in the confusion matrix. The G-mean is another relevant number for measuring the classification accuracy of imbalanced positive and negative samples.

C _ maan	_ \	/sensitivity×specifity	(5	5
u – meun		1	()	"

		Actual Class	
		Negative	Positive
Predicted	Negative	True Negative	False
Class		(TN)	Negative
			(FN)
	Positive	False Positive	True
		(FP)	Positive
			(TP)

Figure 5. Confusion matrix (The authors)

Obviously, the value of the G-mean indicates the performance of the classifier, especially in the imbalanced dataset. The larger the G-mean value, the better the classifier performance.

G. Experimental Results

This section goes over the experiments conducted using the methodology stated in Figure 1 and bank marketing datasets. In the experiments, this study considers the following scenarios; this study explores three distinct experimental scenarios to assess the impact of oversampling and feature selection on the RFC applied for predictive modeling:

• *Scenario 1:* The RFC classifier is initially applied without oversampling, using the input variables, as delineated in Table 1. Subsequently, a feature selection algorithm is employed. This scenario aims to discern the effect of feature selection on the RFC performance.

• Scenario 2: In this scenario, SMOTE is employed as the first step to balance class distributions. Following oversampling, a feature selection algorithm is applied to order the features based on their importance. Finally, the RFC is executed. This scenario was designed to evaluate the potential enhancements achieved by incorporating SMOTE oversampling in the model.

• *Scenario 3:* Similarly to Scenario 2, this scenario employs the random over-sampling (ROS) technique as the initial step, followed by feature selection and ultimately, the RFC. The specific aim of this scenario is to determine the effectiveness of ROS oversampling in improving model outcomes.

Table 1.

H. Environmental Settings

All experiments were performed in a Windows operating system using the R programing language and an Intel R Core TM i5-4200U CPU@ 1.6 GHz 2.30 GHz processor. Each data mining (DM) model underwent ten iterations for robustness and consistency. The R package, a comprehensive suite of software tools for data management, computation, and graphical representation, plays a pivotal role in this analysis. This multifaceted package offers the following key attributes [5]:

• *Efficiency in data handling and storage:* The R package excels in proficiently managing and storing data, ensuring streamlined data manipulation.

• *Array operations:* This provides a set of operators tailored for array operations, with a particular focus on matrices, facilitating complex calculations.

• *Rich toolkit for data analysis:* This substantial collection of intermediary tools caters to diverse data analysis requirements, enhancing the versatility of the R package.

• *Graphical data analysis and visualization:* This package boasts robust capabilities for graphical data analysis and visualization, rendering results both on the computer screen and in print.

• *Interactive data analysis:* R predominantly serves as a platform for crafting novel methods of interactive data analysis. Its

rapid growth is complemented by an array of supplementary packages. Many R programs are designed for transient use and are tailored to specific data analysis tasks.

I. Experimental Setup

In all experiments, 70% of the data are used for training purposes, and the remaining 30% are used for testing purposes and model validation. The process is run ten times with the classifier being tested on the test data each time, and all testing results are reported at the end of the process.

Therefore, three main experiments were performed.

J. Experiment I: Classification without Resampling

In this experiment, the RFC was applied to the dataset without incorporating any oversampling

techniques. The primary objective at this stage was to assess the significance of the dataset's features. Subsequently, the RFC classifier was employed to analyze the classifier's performance when using the top 20 features, all features, the top 15, top 10, and top 5 features. This comprehensive analysis aimed to discern the classifier's behavior under varying feature subsets while avoiding resampling techniques.

The results of this trial are presented in Table 2, with a visual representation provided in Figure 6 for enhanced clarity. A close examination of the findings reveals that the RFC achieved notably high classification accuracy rates, with the top 15 features exhibiting the highest accuracy, followed by the full set of top 20, top 10, and top 5 features. However, it is crucial to note that for datasets characterized by imbalanced class distributions, an evaluation based solely on accuracy may not suffice.

Figure 6. Results of the classifier without sampling (The authors)

To gain a more comprehensive perspective, it

is imperative to consider sensitivity, specificity, and the geometric mean (G-mean). In particular, focusing on sensitivity ratios, which are pivotal for recall of the positive class in this context, the top 15 features demonstrated the most favorable performance with a 62% ratio, closely followed by the top 20 features, top 10 features, and top 5 features, registering ratios of 60.6%, 56.5%, and 50.9%, respectively. These findings shed valuable insights into the classifier's behavior across different feature subsets under the constraints of an imbalanced class distribution.

K. Experiment II: Classification with Oversampling (SMOTE)

In this study, we employ SMOTE to address label imbalance within the dataset. class Subsequently, we apply the RFC to assess the significance of the features. The RFC is then used on varying feature subsets, including the top 20 features (all features), top 15, top 10, and top 5 features, to evaluate its performance following the oversampling procedure. Importantly, the oversampling process is exclusively applied to the training data to ensure fairness in testing using unrepresented or modified data. Different oversampling ratios are explored to identify the optimal resampling ratio. In total, the RFC is trained on different feature subsets (20, 15, 10, 5), resulting in 32 unique outcomes.

The evaluation results of this experiment are presented in Table 2, and Figures 7–10 visually demonstrate the impact of oversampling ratios on classifier performance. Notably, the use of SMOTE oversampling has a limited influence on classification accuracy, as indicated in Figure 7. However, a closer look at the sensitivity values (Figure 8), which are particularly relevant for assessing minority class recall, reveals a steady improvement in classifier sensitivity with oversampling.

Figure 8. Sensitivity (The authors)

 Table 3.

 Importance of features after SMOTE re-sampling (The authors)

Figure 9. Specificity (The authors)

Furthermore, examining the G-mean results in Figures 10 and 11, it becomes evident that the classifier experiences significant enhancements, particularly at the 600% oversampling ratio, with respect to sensitivity and G-mean. Feature selection was conducted after each resampling ratio. The results illustrate feature importance in Table 3. Subsequently, the RFC is applied to the top 20, top 15, top 10, and top 5 features, with the outcomes documented in Table 2. Notably, a slight variation in accuracy was observed above and below the results obtained when all features were used. However, a reduction in the number of selected features leads to a decrease in the sensitivity and G-mean.

Asassfeh et al. Enhancing Imbalanced Data Classification: A Case Study of Portuguese Bank Marketing, Vol. 58 No. 6 Dec. 2023

L. Experiment III: Classification with Random Oversampling (ROS)

In this study, we tackle the challenge of class label imbalance by implementing the random oversampling (ROS) technique on the dataset. Following this, we use the RFC to discern the importance of various features. The RFC is subsequently applied to different feature subsets, specifically the top 20 (comprising all features), top 15, top 10, and top 5 features. The classifier's performance is evaluated after resampling, incorporating varying oversampling ratios to identify the most effective model. To evaluate the classifier's performance, we train it on data oversampled with ROS at various ratios, ranging from 100% to 700%, with a 100% increment at each step. This ratio represents the proportion of instances created from the rare class through ROS. Furthermore, the RFC is trained on different feature subsets at each resampling ratio (20, 15, 10, 5), yielding 32 unique outcomes. The results of this experiment are presented in Table 4, while Figures 11-14 vividly illustrate the impact of the oversampling ratio on the classifier's performance.

Table 4.

Result of the classifier with and without oversampling (ROS) (The authors)

Figure 12. Sensitivity (The authors)

Figure 13. Specificity (The authors)

Notably, Figure 11 demonstrates that ROS oversampling leads to a marginal reduction in

accuracy as the resampling ratio increases. Focusing on sensitivity values (Figure 12), a key metric for assessing minority class recall, we observed a consistent enhancement in the classifier's sensitivity, outperforming the SMOTE technique. Turning our attention to the G-mean results in Figures 14 and 15, we note a slight but consistent improvement in classifier performance, with ROS surpassing SMOTE, and the optimal result achieved at the 600% oversampling ratio for G-mean.

Feature selection is systematically applied after each resampling ratio. The feature importance results are presented in Table 5. The RFC is then applied to the top 20, top 15, top 10, and top 5 features, and the results are documented in Table 4. The analysis reveals a decrease in accuracy when the number of selected features is reduced, which is consistent with the behavior observed for the G-mean.

Comparing the evaluation results in Tables 2 and 4, we observe that feature selection after SMOTE is more reliable than that after ROS. This distinction arises from ROS dependence on a bootstrap approach, which may generate a surplus of replica data.

In this context, the best model for Experiment 2 was achieved with a 500% ROS resampling rate and all features selected, resulting in an accuracy of 89.1% and a G-mean of 0.61. For Experiment 3, the optimal model arises when ROS resampling is set at 500%, with 15 features selected, yielding an accuracy of 87.2% and a G-mean of 0.677.

III. CONCLUSION AND FUTURE WORK

This study addresses imbalanced datasets in the context of predicting long-term deposits

within banking institutions. Through the use of random oversampling (ROS) and SMOTE, the impact of these techniques on enhancing classification model performance and stability was investigated. Experiment 2 showcased SMOTE re-sampling at a 500% ratio, encompassing all features, resulting in a robust model with 89.1% accuracy and a G-mean of 0.61. Conversely, Experiment 3 demonstrated the efficacy of ROS re-sampling at a 500% ratio with the top 15 features, achieving 87.2% accuracy and an impressive G-mean of 0.677.

Comparison with existing literature underscores the effectiveness of ROS and SMOTE methodologies in mitigating imbalanced dataset challenges, showcasing competitive performance. In addition, deliberate feature selection in conjunction with various re-sampling ratios offers nuanced insights into model behavior and sensitivity to feature subsets.

The outcomes have significant practical implications, particularly in domains such as banking and finance, where imbalanced datasets are prevalent. The demonstrated efficacy of ROS and SMOTE techniques, coupled with insights from feature selection, highlights their potential adoption in real-world scenarios. Emphasis on metrics beyond accuracy, including sensitivity, specificity, and G-mean, underscores the importance of a comprehensive evaluation framework in imbalanced classification tasks.

Recommendations include exploring hybrid approaches, integrating multiple re-sampling techniques, and employing advanced ensemble methods for improved predictive performance. Further research avenues include exploring classifiers and additional diverse feature engineering techniques to enhance model robustness against class imbalance. This study's comprehensive evaluation lays the groundwork for future research, facilitating the development of reliable predictive models in the presence of imbalanced datasets.

ACKNOWLEDGMENT

This research was funded by the Deanship of Research and Graduate Studies at Zarqa University, Jordan.
